Word Embeddings
What works, what doesn't, and how to tell the difference for applied research[*]

Arthur Spirling[†]   Pedro L. Rodriguez[‡]

Abstract

We consider the properties and performance of word embeddings techniques in the context of political science research. In particular, we explore key parameter choices—including context window length, embedding vector dimensions and the use of pre-trained vs locally fit variants—in terms of effects on the efficiency and quality of inferences possible with these models. Reassuringly, with caveats, we show that results are robust to such choices for political corpora of various sizes and in various languages. Beyond reporting extensive technical findings, we provide a novel crowd-sourced "Turing test"-style method for examining the relative performance of any two models that produce substantive, text-based outputs. Encouragingly, we show that popular, easily available pre-trained embeddings perform at a level close to—or surpassing—both human coders and more complicated locally-fit models. For completeness, we provide best practice advice for cases where local fitting is required.

Word count: 8408

1

1 Introduction

The idea that words and documents can be usefully expressed as numerical objects is at the core of much modern political methodology. The exact method one uses to model "text as data" has been debated. But in recent times, so called "word embeddings" have exploded in popularity both inside and outside our discipline. The premise of these techniques is beguilingly simple: a token of interest (`welfare` or `washington` or `fear`) is represented as a dense, real-valued vector of numbers. The length of this vector corresponds to the nature and complexity of the multidimensional space in which we are seeking to 'embed' the word. And the promise of these techniques is also simple: distances between such vectors are informative about the semantic similarity of the underlying concepts they connote for the corpus on which they were built. Applications abound. Prosaically, they may be helpful for a 'downstream' modeling task: if consumers search for `umbrellas`, they may also want to purchase `raincoats`, though not `picnic` equipment. Or the similarities may be substantively informative *per se*: if the distance between `immigrants` and `hardworking` is smaller for liberals than for conservatives, we learn something about their relative worldviews.

Exploiting the basic principles behind these examples, word embeddings have seen tremendous success as feature representations in well-known natural language processing problems. These include parts-of-speech tagging, named-entity-recognition, sentiment analysis and document retrieval. Given the generality of those tasks, it is unsurprising that word embeddings are rapidly making their way into the social sciences, political science being no exception. But as is often the case with the transfer of a technology, there is a danger that adoption will outpace understanding. Specifically, we mean comprehension of how well the technology performs—technically and substantively—on specific problems of interest in the domain area of concern. The goal of this paper is to provide that understanding for political science, enabling practitioners to make informed choices when using these approaches.

This broad aim stated, we now clarify our particular focus. As conveyed in our examples above, word embeddings serve two purposes. First they have a 'mere' instrumental function, as

feature representations for some other learning task. So, crudely, while we care that advertising 'raincoats' to those interested in an 'umbrella' improves the user experience, we don't much care *why* this is. That is, we don't have a deep linguistic interest in these terms, or what their nearness tell us about society or its development. Second then, embeddings are a direct object of interest for studying word usage and meaning—i.e. human semantics. Good performance in the former need not, indeed often does not, correlate with good performance in the latter (Chiu, Korhonen and Pyysalo, 2016).

In this paper we focus on this second purpose: embeddings as measures of meaning. The reasoning is simple. First, we cannot pretend to foresee all the downstream use cases to which political scientists will apply embeddings. Moreover, given a well-defined downstream task, how to think about performance is trivial—these are usually *supervised* tasks with attendance metrics measuring accuracy, precision and recall. Second, word usage, including differences between groups and changes over time, is of direct and profound interest to political scientists. There are, however, no well-defined validation metrics beyond those used in the computer science literature which need not apply well to political science and indeed have important limitations (Faruqui et al., 2016).

With this in mind, our specific contribution goes beyond (what we consider) a useful series of results. We propose the framework used to generate them, that will guide researchers through the maze of choices that accompany word embeddings. These include whether to use cheap pre-trained or (more) expensive 'local' corpus trained embeddings. And, within models, we demonstrate the effects of altering core parameters such as context *window size* and *embedding vector length*. In addition to standard predictive performance and computational cost metrics though, we present two novel approaches to model comparison and validation. First, framing the task as an information retrieval one, we show how models may be mechanically compared in terms the words they place close to others—including politics-specific tokens. As a second "gold-standard" approach, we propose a new take on the classical "Turing test" wherein human judges must choose between computer generated nearest neighbors are compared to human generated nearest neighbors. While

we necessarily make certain choices in terms of embedding architecture and which parameters to focus on, we stress the framework herein developed is completely general and not beholden to these choices. It is easily adaptable to evaluate new models—including non-embedding models of human semantics—and other parameter variations.

Our findings are ultimately reassuring for practitioners. In particular, (cheap, readily available) pre-trained embeddings perform extremely well on a multitude of metrics relative to human coding and (expensive) locally trained models for political science problems. This is true beyond our focus *Congressional Record* corpus, and extends even to non-English collections.

We will discuss the choices practitioners faces momentarily. Before doing that, we provide a brief overview of the embeddings literature to clarify terms for what follows.

2 Word Embeddings in Context

The methods to implement word embeddings in a scalable way are new. The central theoretical concepts are not. Indeed, modern incarnations of these models find common ground in the distributional semantics literature dating back to at least the 1950s (e.g. Wittgenstein, 1953; Harris, 1954; Firth, 1957). They now go by various names: semantic vector space models, word space models or—our preferred nomenclature—distributional semantic models (DSMs).

2.1 Local Windows: The Distributional Hypothesis

The key insight of the early theoretical work was that we can "know a word by the company it keeps" (Firth, 1957, 11). More concretely, a word's meaning can be garnered from its contextual information: literally, the other words that appear near it in text. Formalizing this idea, the "distributional hypothesis" suggests that words which appear in similar contexts are likely to share similar meanings (Harris, 1970). A "context" here would typically mean a symmetric window of terms around the word of interest.

Confusingly, techniques that use local windows are sometimes written of as if they are syn-

onymous with DSMs. But this is wrong. In particular, when DSMs for large corpora took off empirically in the 1990s, the distributional insight was applied in very different ways. Notable efforts include Latent Semantic Analysis (Landauer and Dumais, 1997), Hyperspace Analogue to Language (HAL) (Lund and Burgess, 1996) and Latent Dirichlet Allocation (LDA) (Blei, Ng and Jordan, 2003). Of these, LDA and its variants (e.g. Quinn et al., 2010; Roberts et al., 2014) have proved extremely popular in social science but the implementations of this technique do not require (nor typically recommend) local windows of text within documents.

2.2 Embeddings: Neural Models

While the logic of local windows is straightforward to describe, systematic modeling of word sequences is extremely challenging. The key innovation, provided by Bengio et al. (2003), was conceiving of words as distributed representations within a neural language model. Here 'neural' means based on a (artificial) neural network, a very flexible framework for learning relationships that has appeared in some political science contexts (e.g. Beck, King and Zeng, 2000). The Bengio et al. approach maps words to real-valued vectors. Intuitively, each element of those vectors represents some hypothetical characteristic of the word(s). The vector for a given word can be called a *word embedding*.

These vectors are obviously conceptually and practically different to those of the 'vector space model' well-known to political scientists. For one thing, word embedding vectors are, per their name, for *words*. The vector space model has each *document* as a vector. In addition, the embedding vectors are the *result* of applying a model, whereas the document vectors are the *input* to one. Building on Bengio et al. (2003), and key for our interests, Collobert and Weston (2008) (see also Collobert et al., 2011) demonstrated that while word embeddings are useful for downstream tasks, they also carry substantive syntactic and semantic information about language *per se*. Again this is a conceptual shift from the traditional vector space modeling in political science. There, words are discrete symbols. Their meaning is exogenous to the endeavor at hand, and we simply count (in various ways) their occurrence. In the embeddings literature, the meaning of words is itself a

5

quantity that can be *learned*; furthermore their vector representations often allows for simple but informative mathematical operations. A textbook case is to note that (certain) embeddings can produce analogies like `king` - `man` + `woman` ≈ `queen`, where each term is represented as vector in *D* dimensional space. But there was a second advancement in this work: the authors alleviated a methodological problem that made earlier estimation (by e.g. Bengio et al., 2003) very slow.

2.3   The rise and rise `Word2Vec` and `GloVe`

Mikolov et al. (2013) took the logic of the Bengio et al. (2003) model, but focused solely on producing accurate word representations. These authors reduced the complexity of the model, and allowed for its scaling to huge corpora and vocabularies. Released as a set of models called `Word2Vec`, this work is so popular that it has confusingly become almost synonymous with both embeddings and DSM. Beyond modeling improvements, `Word2Vec` included several preprocessing steps that are key to its performance. Soon after its release, Pennington, Socher and Manning (2014) proposed a competing algorithm—Global Vectors, or `GloVe`—that showed improved performance over `Word2Vec` in a number of tasks. Despite having different building blocks (`Word2Vec` is based on a shallow neural net, `GloVe` is based on co-occurrences), the two approaches are not mathematically very different. In what follows below, we will therefore focus on using `GloVe` solely—but we anticipate essentially identical results were a researcher to use one of the `Word2Vec` infrastructures.

Both camps released software that allowed researchers to use pre-trained embeddings (fit to a corpus such as the English entries on Wikipedia) or estimate their own. This latter scenario may be alternatively expressed as saying that analysts are fitting one of the models 'locally' to their particular corpus. Regardless of the specific implementation, initial comparative studies suggested word embedding models resoundingly outperform traditional DSMs in a range of tasks (Baroni, Dinu and Kruszewski, 2014), though these claims have been subsequently moderated.

3 Embedding Models and Parameter Choices

The application of any statistical model requires choices; embeddings are no exception. For political scientists downloading code (or indeed downloading pre-fit embeddings), at the very least, they need to decide:

1. how large a **window size** they want the model to use.

2. how large an **embedding** they wish to use to represent their words.

3. whether to fit the embedding models **locally**, or to use **pre-trained** embeddings fit to some other (hopefully related) corpus.

We now discuss the nature of these choices. In addition, we explain some other important features of embeddings for researchers: namely, the fact that embeddings demonstrate *instability* in practice, and what one might do about this. In general, we note that there is often little guidance in the literature as to how decisions should be made—and virtually none at all for social science problems. A final caveat here is that, of course, there are many other parameter choices beyond the ones we specify in this section; for example, `Word2Vec` allows one to choose a learning rate for its backpropogation algorithm, and all models can use documents that have been preprocessed differently. Using our methods below, users can make decisions over them in the same way. But we keep our focus on the three above because they seem most central to empirical research.

3.1 Window-size

Window-size determines the number of words, on either side of the focus word to be included in its context.[1] The type of semantic relationship captured by embeddings has been found to vary with window-size, with larger window sizes (> 2) capturing more topical relations (e.g.

---

[1] Context windows can also be asymmetric, in which case window-size refers to the number of words on one side of the focus word to be included in its context. Asymmetric windows are better able to account for word order which may be useful for some tasks. Pennington, Socher and Manning (2014) for example find asymmetric windows to produced embeddings better suited for syntactic tasks. Nevertheless, symmetric windows are the default option for most use cases.

`Obama - President`) and smaller window sizes (< 2) capturing syntactic relations (e.g. `dance - dancing`).

For topical relationships, larger windows (usually 5 or above) tend to produce better quality embeddings although with decreasing returns—a result highlighted by Mikolov et al. (2013) and which we corroborate below. Intuitively, larger contexts provide more information to discriminate between different words.[2] Take, for example, the following two sentences: `cows eat grass` and `lions eat meat`. A window-size of 1 does not provide enough information to distinguish between `cows` and `lions` (we know they both `eat`, but we don't know what) whereas a window-size of 2 does.

3.2 Embedding Dimensions

This parameter determines the dimensions of the embedding vectors which usually range between $50 - 450$. We can think of these dimensions as capturing different aspects of "meaning" or semantics that can be used to organize words.[3] Too few dimensions—imagine the extreme of 1—and there can be no meaningful separability of words; too many, and some dimensions are likely to be redundant (go unused). Factors such as vocabulary size and topical specificity of the corpus are likely to play a role, although theoretical work in this area remains scant.[4] Empirically, more dimensions generally improve performance across a wide variety of tasks but with diminishing returns. Interestingly, extant literature suggests that the point at which improvements become marginal differs depending on the problem. For downstream tasks optimal performance can sometimes be reached with as few as 50 dimensions (Melamud et al., 2016). Semantic tasks, on the other hand, continues show significant improvements until around $200 - 300$ dimensions after which improvements are marginal (Pennington, Socher and Manning, 2014).[5] This difference is

---

[2]See Supporting Information C for a quick empirical verification of this claim for real data.

[3]Thinking of "meaning" in terms of dimensions in Euclidean space dates back at least to Osgood, 1952.

[4]Of the few that we could find, Patel and Bhattacharyya (2017) posit that the number of pairwise equidistant words of the corpus vocabulary measured using the term co-occurrence matrix provides a lower bound on the number of dimensions. It is not entirely clear what this equidistant metric means substantively.

[5]Readers may recall, 300 is also the optimal number of dimensions in LSA (Landauer and Dumais, 1997).

likely a result of downstream tasks leveraging specific aspects of meaning—for example, a sentiment classification task will likely benefit from embeddings that focus on discriminating words along affect-related dimensions.

3.3 Pre-Trained Versus Going Local

Embedding models can be data hungry, meaning they need a lot of data to produce 'useful' results. Consequently, researchers with small corpora often use pre-trained embeddings. This also avoids the overhead cost associated with estimating and tuning new embeddings for each task. However, there are trade-offs. Pre-trained embeddings need not capture well the semantics of domain-specific texts. Intuitively, we want to use embeddings estimated using a corpus generated by a similar "language model" to that which generated our corpus of interest. The more similar the two language models, the more the underlying semantics. For a highly specific corpus—a corpus in Old English for example—it may make sense to train a local model.

Li et al. (2017) compare the performance of embeddings trained on different corpora for Twitter sentiment analysis. They find that embeddings trained on the Google News corpus perform worse—measured in terms of accuracy—than embeddings trained on Twitter data. This motivates an argument that twitter data is different. However, those also find that embeddings trained on Google News *and* Twitter data perform the best. This suggests more information is better. On the other hand, Diaz, Mitra and Craswell (2016) find that specialized embeddings—trained on a relevant subset of documents—outperform global embeddings in information retrieval tasks.[6]

An alternative to training locally is to "retrofit" global (pre-trained) embeddings to include additional information. Faruqui et al. (2014) retrofit pre-trained vectors using existing semantic lexicons such as `WordNet`, `FrameNet`, and the Paraphrase Database. They find this additional information improves performance in the standard lexical evaluation tasks. Retrofitting can also be task-specific. Kiela, Hill and Clark (2015) retrofit pre-trained embeddings to improve performance

---

[6]The superiority of using specialized versus global information has been well established in the information retrieval literature Attar and Fraenkel (1977); Xu and Croft (1996); Hull (1994).

in *similarity* and *relatedness* tasks—two different tasks—using an online Thesaurus (MyThes) and lists of free association norms for each task respectively.[7] Similarly, Yu et al. (2017) specialize word embeddings to perform sentiment analysis by retrofitting pre-trained embeddings using lists of valence norms. One final alternative is to initialize locally-trained models with pre-trained embeddings, relaxing data constraints. Again, this only makes sense if the underlying language models are not too dissimilar.

In this paper we compare the set of embeddings from a set of locally trained models using a political corpus to one of the more popular pre-trained embeddings available—`GloVe`. Our results show high correlations between both models, suggesting pre-trained embeddings may be appropriate for certain political corpora. However, we stress that researchers need be conscious and transparent regarding the implied assumptions when deciding to use pre-trained embeddings.

3.4 Instability

Word embeddings are known to be unstable (Wendlandt, Kummerfeld and Mihalcea, 2018). That is, the embedding space of two models trained on the same corpus and with the same parameter choices may differ substantially—a fact we will observe empirically below. This instability can be particularly problematic when drawing qualitative inferences from the embeddings themselves, with equivalent models producing widely different nearest neighbor rankings. Underlying this instability are various sources of randomness in the estimation of word embeddings, most notably random initialization of the embedding vectors and random order of training documents. While all words are affected, some are more affected than others (Wendlandt, Kummerfeld and Mihalcea, 2018; Pierrejean and Tanguy, 2018). It is worth noting that `GloVe` has been found to be more stable than `Word2Vec`, probably because of its use of a global co-occurrence matrix rather than an online local window context (Mimno and Thompson, 2017; Wendlandt, Kummerfeld and Mihalcea,

---

[7]Kiela, Hill and Clark (2015) also evaluate joint-learning models in which embeddings are estimated using both the corpus and the additional semantic lexicons. They do not find a significant performance difference compared to retrofitting.

2018).[8]

To account for the inherent instability in the estimation process we recommend researchers estimate a given model over *multiple initializations* of the corpus—we use ten—and use the average of the metric of the metric of interest. We accept that variation between realized embeddings is simply a fact of life; nonetheless, for what follows we presume that researchers want to know how stability correlates with model specification.

4   Evaluating Embedding Models for Social Science

As noted above, researchers face as least three "big" choices when producing word embeddings. To evaluate which choices are optimal we need evaluation tasks. For word embeddings tasks fall into one of two categories: *extrinsic* and *intrinsic*.[9] These correspond to the two main use cases of embeddings: as feature inputs and as models of semantics. Recall that our focus in this paper is on the second case.

Extrinsic tasks include various downstream NLP problems such as parts-of-speech tagging, named-entity-recognition, sentiment analysis and document retrieval. These are usually supervised, and have well-defined performance metrics. For this paper we considered evaluating embeddings this way. However, it was not immediately obvious to us which tasks, if any, represented good baselines for political scientists.[10] As noted by Denny and Spirling (2018), there has been very low take up of supervised learning problems in political science relative to unsupervised learning problems. Moreover, as noted above, evidence of good performance need not generalize. How much should a researcher in IR update when informed that a given embedding model performs well in a classification task of congressional speeches? Given a well-defined downstream task, we

---

[8]Separate to instability, it is reasonable to expect embeddings to differ as a result of *sampling variability*. If we view any given corpus as a particular instantiation of a superpopulation of linguistic entities, then we should adjust for this with the equivalent of a standard error. See Antoniak and Mimno (2018) for bootstrapping ideas pertaining to this problem.

[9]It is worth noting that performance in intrinsic tasks need not translate into good performance in extrinsic tasks (Chiu, Korhonen and Pyysalo, 2016).

[10]The lack of consensus extends beyond political science (Nayak, Angeli and Manning, 2016).

recommend users first consider pre-trained embeddings if reasonably appropriate—unlikely if the corpus of interest is in Old English—before proceeding to tune a locally trained model.

Intrinsic tasks evaluate embeddings as models of semantics. These include word analogy— algebraic operations are performed using word vectors to answer questions such as "France is to Paris as Germany is to..."; word similarity—pairs of words along with their human provided similarity ratings are compared to similarity ratings computed using word embeddings; synonym tests—TOEFL multiple-choice synonym questions; noun-clustering—a similarity measure is used to assign words to a pre-defined number of semantic classes; sentence completion (specific to the Skip-Gram architecture)—select from multiple choices to fill in the missing word in a sentence. These tasks require human generated data. Researchers tend to rely on existing datasets that are either freely available online or can be requested from the original authors. However, this can be problematic as existing datasets may be ill-suited to a particular corpus or for a particular seman- tic relation of interest. For example, word similarity datasets often do not differentiate between the various ways in which two words can be related (Faruqui et al., 2016).[11] Moreover, seman- tic relationships are likely to vary as a function of demographics (Halpern and Rodriguez, 2018; Garimella, Banea and Mihalcea, 2017), yet few datasets have information on the background char- acteristics of the subjects. The role of demographics or other background characteristics, including partisanship, is of particular relevance to social scientists. Indeed, these differences are precisely what we are interested in! Below we make the case for crowdsourcing as a flexible alternative allowing researchers to tailor the tasks to specific objectives and gather demographic information when appropriate (Benoit et al., 2016; Schnabel et al., 2015).

We compare models using four criteria:

1. technical criteria —model loss and computation time;

2. model variance (stability)—within-model Pearson correlation of nearest neighbor rankings

---

[11]Agirre et al. (2009) distinguish between similarity—as in coffee and tea—and relatedness—as in cup and cof- fee. Words can be related syntactically or semantically (Mikolov et al., 2013; Baroni, Dinu and Kruszewski, 2014). According to structuralist theory words can have paradigmatic —words that tend to occur in similar contexts— and syntagmatic —words that tend to co-occur— relations (Saussure, 1959; Sahlgren, 2008).

across multiple initializations;

3. query search ranking correlation—Pearson and rank correlations of nearest neighbor rankings;

4. human preference— a "Turing test" assessment and rank deviations from human generated lists

The latter two criteria can also be used to compare pre-trained embeddings with locally-trained embeddings, which we do. To illustrate this framework, we compare pre-trained embeddings to a set of locally trained embedding models varying in two parameters: embedding dimensions and window-size. Before proceeding with our estimation framework we discuss each criteria in greater depth.

4.1 Technical Criteria

The most straightforward metric to compare different models is prediction loss at the point of convergence (i.e. when training stops). Specifically we look at both in-sample and out-of-sample (test-set) loss. For this, we consider window-size a tuning parameter. As noted above, the choice of window-size may be informed by the type of semantic relation of interest—syntactic or topical. If a specific window-size is chosen on theoretical grounds—whatever they may be—then it would no longer be a tuning parameter and it would be unreasonable to compare models of different window-sizes. Instead we opt to choose window-size as a function of model performance. If the intuition motivating `GloVe` is correct, namely that meaning is strongly connected to co-occurrence ratios, then the window-size that optimizes the correspondence between the embedding vectors and the global co-occurrence statistics should produce the highest the more "meaningful" embeddings. Generally speaking, larger window sizes and more dimensions both translate into longer computation times, resulting in a performance vs computation time tradeoff. We therefore also compare the set of locally-trained models with respect to computation time in minutes.

13

4.2 Stability

As we discussed above, embedding models are unstable. This is likely to vary for different parameter choices. To quantify this instability we look at the Pearson correlation of nearest neighbor rankings across a set of different vector initializations for each combination of parameter choices. Given ten separately estimated models for a given parameter pair, we have 45 pairwise correlations for each model ($\frac{n(n-1)}{2}$, or the lower diagonal of the 10×10 correlation matrix). We compare the distribution of these pairwise correlations across models. Below we provide more detail as to how we arrive at these samples and the overall estimation framework.

4.3 Query Search Ranking Correlation

While prediction loss is informative, it is not obvious how to qualitatively interpret a marginal decrease in loss. Ultimately, we are interested in how a given embedding model organizes the semantic space relative to another. To evaluate this, we appeal to the information retrieval literature. A common objective in information retrieval problems is to rank a set of documents in terms of their relevance to a given query. In our case we are interested in how two models rank words in a common vocabulary in terms of their semantic similarity with a given query term. One potential measure is the intersection over the union (IoU) — also known as the *Jaccard Index*— between the set of top N nearest neighbors for a given target word (see, e.g., Sahlgren, 2006; Pierrejean and Tanguy, 2017). For example, take the following two sets of top 5 nearest neighbors for the target word `democracy`: $A = \{$ `freedom`, `democratic`, `ideals`, `vibrant`, `symbol`$\}$ and $B = \{$`freedom`, `democratic`, `dictatorship`, `democratization`, `socialism`$\}$. Given two nearest neighbors in common, the IoU is $\frac{|A \cap B|}{A \cup B} = \frac{2}{8} = 0.25$. The problem with using the IoU Index is that it is highly sensitive to the choice of N and there is no principled way of choosing N. Moreover, the IoU does not take into account rank order. There may be cases where the IoU is appropriate—when N is well-defined and order is irrelevant—but for the comparisons below we opt for comparing the entire ranking—all words in the common vocabulary—for a set of predefined query terms. We do so using both Pearson correlation and rank correlation. The higher these correlations, the more

similar the embedding spaces of both models. Below we discuss how we went about choosing the query terms.

4.4   Human Preferences

The output of distributional models with strong predictive performance need not be semantically coherent from a human standpoint. This point was illustrated by Chang et al. (2009) in the case of topic models. For this reason we make a clear distinction between predictive performance and semantic coherence, and propose separate metrics to evaluate both.

4.4.1   Turing Assessment

To evaluate semantic coherence we draw inspiration from the fundamental principles laid out by Turing (1950) in his classic article on computer intelligence. In that context, a machine showed human-like abilities if a person engaging in conversation with both a computer and a human could not tell which was which. We use that basic intuition in our study. In particular, an embedding model achieves "human" performance if human judges—crowd workers—cannot distinguish between the output produced by such a model from that produced by independent human coders. In our case, the idea is not to "fool" the humans, but rather to have them assert a preference for one set of outputs over another. If a set of human judges are on average indifferent between the human responses to a prompt and the model's responses, we say we have achieved human performance with the model. By extension, a model can achieve *better than human* performance by being on average preferred by coders. Naturally, models may be *worse than human* if the judges like the human output better.

Before getting into specifics, it is helpful to clarify some aspects of the intuition. First, there is a superficial similarity between our approach and more conventional supervised learning problems. This is misleading. In those arrangements, the researcher employs humans to hand-code a training set. Then they use a model to learn the relationships between the covariate features of the data and the class labels given by the humans. After this, the analyst sees how well the machine can predict

"held out" human labels in a test set. The machine's performance can then be directly assessed in terms its ability to replicate the human judgments for each case. But this is not what we are doing. Instead, we ask whether humans themselves, on seeing a statistical model's best attempt to describe a concept, find that representation reasonable relative to one produced by other humans. Second, while the Turing test connotes a human versus machine contest, the approach here is more general. Indeed, any output can be compared to any other—including where both sets are produced by a model or both by humans—and conclusions drawn about their relative performance as judged by humans.

The steps we take to assess the relative Turing performance of the models are as follows:

1. **Human generated nearest neighbors:** For each of the ten political prompt words above have humans—crowd workers on Amazon MTurk—produce a set of nearest ten neighbors— we have 100 humans perform this task. Subsequently rank "human" nearest neighbors for each prompt in terms of the number of mentions and choose the top 10 for each prompt.

2. **Machine generated nearest neighbors:** For the embedding model under consideration— pre-trained or some variant of the locally fit set up—produce a list of ten nearest neighbors for each of the ten given prompt words above.[12]

3. **Human rating:** Have a separate group of humans perform a Triad task —135 subjects on average for each model comparison— wherein they are given a prompt word along with two nearest neighbors —a computer and a human generated nearest neighbor— and are asked to choose which nearest neighbor they consider better fits the definition of a context word.[13]

4. **Compute metric:** For each prompt compute the expected probability of the machine generated nearest neighbor being selected and divide by 0.5. This index will range between 0 and 2. A value of 1 implies the embedding model is on par with human performance (i.e.

---

[12]It is common in the literature to focus on the *top ten* nearest neighbors. See for example McCarthy and Navigli (2007) and Garimella, Banea and Mihalcea (2017).

[13]See Appendix for the exact wording of the task.

a human rater is equally likely to choose a nearest neighbor generated by the embedding model as one generate by another human).

In most cases there is some overlap in the set of nearest neighbors being compared. The comparisons we show subjects never include the same nearest neighbor for both models; in these cases we assume either model has 50% chance of being selected. This requires we adjust the expected probability of a machine generated nearest neighbor being selected by the probability of the triad task showing the same nearest neighbor for both machine and human. For both tasks above—collecting human generated nearest neighbors and the triad task—we created specialized `RShiny` apps that we deployed on MTurk. For the triad task we paid subjects $1 to perform 13 such comparisons—one for each of our political prompt words, one trial run and two quality checks; for the word generation task we paid subjects $3 to generate 10 associations for each of the ten political prompts. The code for both apps is available from our GitHub.

4.4.2 Log Rank Deviations

Using the set of human generated lists we can compare the aggregate human ranking of each nearest neighbor—as determined by token counts—with their equivalent rank on a given embedding space. So for example, if for the query `democracy` the word `freedom` is ranked 3rd according to human counts and 7th according to a given embedding space, we say it's log rank deviation is $\log((7-1)^2)$. We compute this deviation for every token mentioned by our subjects for each of our politics queries and compute an average over the set of queries for every model.[14]

5 Estimation Setup

Obviously, we need a data set on which to operate, and a particular way to model the embeddings. For the latter, as noted above, we choose `GloVe` simply because it seems more popular with so-

---

[14]It may be worth limiting this to tokens mentioned by at least *N* subjects, but here we avoid making additional parameter choices.

cial scientists,[15] though we have no reason to believe our results below would differ much under `Word2Vec`. For the data we focus on a medium sized corpus of around 1.4 million documents from American politics—though as we will see our findings are portable to other political contexts and indeed other languages.

Below we will extend our analysis to other corpora and other languages, but for now we focus in detail on a collection we deem somewhat representative of political science efforts in this area. In particular, the set of *Congressional Record* transcripts for the 102nd–111th Congresses (Gentzkow, Shapiro and Taddy, 2018). These contain all text spoken on the floor of both chambers of Congress. We further restrict our corpus to the set of speeches for which party information is available.[16] We do minimal preprocessing: remove all non-text characters and lower case. Next we subset the vocabulary. We follow standard practice which is to include all words with a minimum count above a given threshold—between 5-10 (we choose 10). This yields a vocabulary of $91,856$ words.[17]

5.1 Implementing Choices

We focus our analysis on two hyperparameter choices and all 25 combinations, though to reiterate the framework we lay out is not specific to these parameter pairs:

1. window-size—1, 6, 12, 24 and 48 and

2. embedding dimension —50, 100, 200, 300, 450

To account for estimation-related instability we estimate 10 sets of embeddings for each hyperparameter pair, each with a different randomly drawn set of initial word vectors. In total we estimate 250 different sets of embeddings. The only other hyperparameter choices we make and leave fixed are the *number of iterations* and *convergence threshold*. We set the maximum number of iterations to 100 and a use a convergence threshold of 0.001 such that training stops if either the

---

[15]In particular, the `GloVe` pre-trained available on February 2, 2019 from https://nlp.stanford.edu/projects/glove/, for which the training corpus is Wikipedia 2014 and Gigaword 5.

[16]Focusing on this subset reduces our corpus by around a third.

[17]The pre-trained `GloVe` vocabulary consists of $400,000$ tokens.

maximum number of iterations is reached or the change in model loss between the current and preceding iterations is below the convergence threshold. None of our models reached the maximum number of iterations. We set all remaining hyperparameter values at their default or suggested values in the `Glove` software.

5.2 Query Selection

Above we explained that a natural auxiliary quantity of interest is the set of nearest neighbors of a given word in the embeddings space. These form the core of our comparison metric in the sense that we will want to know how similar one set of nearest neighbors from one model specification is to another. And, by extension, how "good" one set of nearest neighbors is relative to another in terms of a quality evaluation by human judges. We use two sets of queries: a random sample of 100 words from the common vocabulary and a set of 10 curated political terms.[18]

For the politics-specific queries, we hand-picked 10 terms—prior to performing any evaluations needless to say. First, there are series of concept words that we suspected would be both easily understood, but also exhibit multiple different meanings depending on who is asked: `democracy`, `freedom`, `equality`, `justice`. Second, there are words pertaining to policy issues that are debated by political parties and motivate voting: `immigration`, `abortion`, `welfare`, `taxes`. Finally, we used the names of the major parties, which we anticipated would produce very different responses depending on partisan identification: `republican`, `democrat`. Obviously, these words are somewhat arbitrary; we could have made other choices. And indeed, we would encourage other researchers to do exactly that. Our prompts are intended to be indicative of what we expect broader findings to look like, and to demonstrate the utility of our generic approach.

---

[18]A more systematic approach would compare the entire vocabulary (see for example Pierrejean and Tanguy (2017)). We found this prohibitively expensive and ultimately unnecessary. A random sample of 100 words should approximate well-enough the comparisons of interest.

6 Results: Performance Compared

This section reports the results for the evaluation metrics outlined in section 4. We begin with the technical criteria.

6.1 Technical Criteria

Figure 1a displays the mean—over all ten initializations—minimum loss achieved for all sixteen parameter pairs we considered. Consistent with previous work, more dimensions and larger window-sizes both unconditionally improve model fit albeit with decreasing returns in both parameter choices. Except for very small window-sizes (< 6), improvements become marginal after around 300 dimensions. Unequivocally, researchers ought avoid combining few dimensions (< 100) with small window-sizes (< 6). Keep in mind, however, that using more dimensions and/or a larger window-size comes at a cost, longer computation time (see Figure 1b). The largest of our models ($48 - 450$) took over three hours to compute parallelizing over eight cores.[19] This seems reasonable if only computing once and having access to several cores, but can become prohibitive when computing over several initializations as we suggest.[20] In this light, the popular parameter setting $6 - 300$ (window size 6, vector length 300) provides a reasonable balance between performance and computation time.

6.2 Stability

We next compare all parameter pairs with respect to the stability of the resulting embeddings. Figures 2a plots the distribution of Pearson correlations for the 100 random queries. Models with larger window-sizes produce more stable estimates—higher average Pearson correlation and lower interquartile range—but only up to a point. As the number of dimensions increase, the difference in stability between different window sizes decreases and eventually flips—larger window sizes result

---

[19]At the time of writing, a standard laptop has 4 cores available. Keep in mind computation time will be a function of the stopping conditions specified—number of iterations and convergence threshold. 100 iterations and a convergence threshold of 0.001 may be considered too conservative.

[20]Unless the researcher has access to a high-performance cluster (as we did) and is able to parallelize.
(a) Mean Minimum Loss Achieved
(b) Computation Time (minutes)

Figure 2: Stability Criteria

in greater instability. This parabolic relationship between window-size, number of dimensions and stability is likely a function of corpus size and token frequency.[21] For the set of 10 politics queries we observe the same trends although do not reach the point at which the relationship reverses (see Figure 2b).

6.3 Query Search Ranking Correlation

Clearly different parameter choices produce different results in terms of performance and stability, but what do these differences mean substantively? To answer this question we turn to comparing models with respect to how they rank query searches. Figure 3a displays a heatmap of pairwise correlations for all models, including `GloVe` pre-trained embeddings, for the set of random queries.[22] We observe high positive correlations (> 0.5) between all local models. Correlations are generally higher between models of the same window-size, an intuitive result, as they share the underlying co-occurrence statistics. Somewhat less intuitive, comparing models with different window-sizes, correlations are higher the larger the window-size of the models being compared (e.g. 6 and 48 vis-a-vis 1 and 6). Correlations are larger across the board for the set of political

---

[21]For the State of the Union, a much smaller corpus below, we find the flip occurs after 100 dimensions.

[22]As pretrained embeddings we use the 6-300 GloVe embeddings.

queries (see Figure 3b). These results suggest the organization of the embedding space is most sensitive to window-size but this decreases quickly as we go beyond very small window-sizes (i.e. models with window-size of 6 and 48 show much higher correlation than models with window-size of 1 and 6).

The last column of Figures 3a and 3b compare `GloVe` pre-trained embeddings with the set of local models. For this comparison we subsetted the respective vocabularies to only include terms common to both the local models and the pretrained embeddings.[23] As would be expected, correlations are lower than those between local models, yet they are still surprisingly large—especially for local models with larger window-sizes and for the set of political queries (all above 0.5). Our reading is that `GloVe` pre-trained embeddings, even without any modifications (Khodak et al., 2018), may be a suitable alternative to estimating locally trained embeddings on present-day political corpora. This is good news for political scientists who have already relied on pre-trained embeddings in their work.

As a final check, we looked at whether pre-trained embeddings might do a 'worse' job of reflecting highly specific local embeddings for our focus corpus. In this case, we mean party: it could in principle be the case that while pre-trained embeddings do well in aggregate for the *Congressional Record* they do poorly for Democrats or Republicans specifically. To evaluate this we estimate a set of additional local models (again, 10 for each group and using 6-300 as parameter settings) for subsets—by party—of the aggregate corpus. We find no statistically significant differences in correlations for the politics queries (see Supporting Information D).

6.4 Human Preferences

Recall that human raters represent our gold-standard evaluation metric, and we assess performance here on two different types of tasks.

---

[23]In the appendix we include additional comparisons without subsetting the vocabularies.
(a) Random Queries
(b) Politics Queries

Figure 3: Query Search Ranking Criteria
6.5 Turing Assessment

Figures 4a– 4d measure performance of a "candidate" model relative to a "baseline" model. Recall, values above (below) 1 mean nearest neighbors from the "candidate" model were more (less) likely to be chosen by human raters. A value of 1 means human raters were on average indifferent between the two models. Figure 4a compares two local models: $48 - 300$ (candidate) and $6 - 300$ (baseline). There is no unqualified winner. We see this as consistent with previous metrics—these models have a 0.92 correlation (see Figure 3b).

How do local models fare against human generated nearest neighbors? Except for one query (`immigration`), the local model of choice—6-300—shows *below-human* performance for all but two of the queries. On average, for the set of ten political queries, the local model achieves 69% (std devn= 0.20) of human performance. Turning to pre-trained `GloVe` embeddings, we observe that they are generally preferred to locally trained embeddings (see Figure 4c). Moreover, pre-trained embeddings are more competitive against humans—albeit with greater variance—achieving an average of 86% (std dev $= 0.23$) of human performance.
(a) Candidate: Local 48-300

Baseline: Local 6-300

(b) Candidate: Local 6-300

Baseline: Human
(c) Candidate: GloVe

Baseline: Local 6-300

Baseline: Human

Figure 4: Human Preferences-Turing Assessment

6.6 Log Rank Deviations

Using the log rank deviation measure, we can compare all models given our set of human generated lists (see Figure 5). Results generally mirror those obtained using our technical loss criterium, barring the large confidence intervals. Models with larger windows and more dimensions show lower log rank deviations, indicating better performance but with decreasing returns. This suggests

a strong correspondence between predictive performance and semantic coherence as hypothesized by the distributional hypothesis.
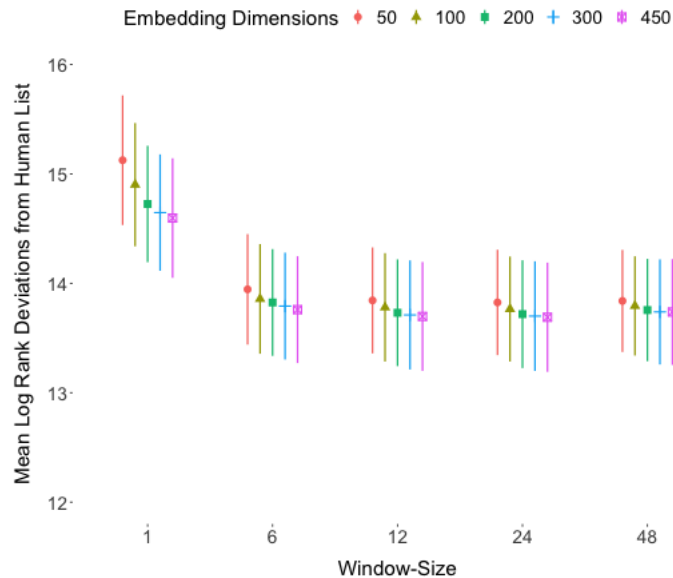

Figure 5: Human Preferences-Log Rank Deviations

7 Other Corpora, Other Languages

Our core results presented, we now extend our evaluation to four other corpora, varying in size and language. These are:

1. the full set of speeches from the UK Parliament for the period $1935 - 2016$ obtained from Rheault et al. (2016)

2. all State of the Union (SOTU) speeches between 1790 and 2018

3. the full set of speeches from both chambers of the Spanish Legislature —*Cortes Generales*— for the V - XII legislatures.[24] As political queries we use: `democracia`, `libertad`, `igualdad`, `equidad`, `justicia`, `inmigracion`, `aborto`, `impuestos`, `monarquia`, `parlamento`.

---

[24] As the XII was ongoing at the time of writing we used all speeches available up until Oct-18.

4. the full set of speeches from the German Legislature—*Deutscher Bundestag*— for the election periods 14 - 19.[25] The political queries in this case are: `demokratie`, `freiheit`, `gleichberechtigung`, `gerechtigkeit`, `einwanderung`, `abtreibung`, `steuern`, `cdu` and `spd`.

We did not find readily available pre-trained embeddings in German, as such all our comparisons in this case are between locally trained embeddings. Both the Spanish and German corpora are original datasets collected for the purposes of this paper.[26]

Table 1 provides summary statistics for these corpora and the *Congressional Record* corpus. We can see that the SOTU corpus is substantially smaller than all the other corpora and also encompasses a much longer time period.

Corpus	Period	Num. of Docs.	Num. of Tokens	Avg. Tokens/Doc.	Vocab. Size
Congressional Record	1991 - 2011	1,411,740	3.4×10^8	238	91,856
Parliamentary Speeches	1935 - 2013	4,455,924	7.2×10^8	162	79,197
State of the Union	1790 - 2018	239	2.0×10^6	8143	11,126
Spanish Legislature	1993 - 2018	1,320,525	3.0×10^8	224	94,970
German Legislature	1998 - 2018	1,193,248	0.8×10^8	69	108,781

Table 1: Corpora Summary Statistics

In Supporting Information E, we provide the same results plots as we gave for our *Congressional Record*. Perhaps surprisingly, but no doubt reassuringly, these are almost identical to the ones above. That is, when we look at the embedding models we fit to these very different corpora, the lessons we learn in terms of hyperparameter choices, stability and correlations across search queries (i.e. on the issue of whether to fit local embeddings, or to use prefit ones) are the same as before. Of course, there are some exceptions: for example, we do find models of window-size equal to one perform well in the case of the SOTU corpus and for the German corpus—though to a lesser extent.

---

[25] As the 19th *Wahlperiode* was ongoing at the time of writing we used all speeches available up until Oct-18.

[26] We have made these publicly available, and these may be downloaded via the project's github page.

8 Advice to Practitioners

In this section we summarize our results in terms of what we deem the main takeaways for practitioners looking to use word embeddings in their research. First, in terms of 'choice' parameters in applied work:

- **Window-size and embedding dimensions:** with the possible exception of small corpora like the State of the Union speeches, one should avoid using very few dimensions (below 100) and small window-sizes (< 5), especially if interested in capturing topical semantics. While performance improves with larger window-sizes and more dimensions, both exhibit decreasing returns—improvements are marginal beyond 300 dimensions and window-size of 6. Given the tradeoff between more dimension/larger window-size and computation time, the popular choice of 6 (window-size) and 300 (dimensions) seems reasonable. This particular specification is also fairly stable meaning one need not estimate multiple runs to account for possible instability.

- **Pre-trained vs local embeddings:** `GloVe` pre-trained embeddings generally exhibit high correlations (> 0.4 for the set of random queries and > 0.65 for the set of curated queries) with embeddings trained on our selection of political corpora.[27] At least for our focus *Congressional Record* corpus, there is little evidence that using pre-trained embeddings is problematic for subdivisions of the corpus by party—Republican vs Democrat speech.

  Human coders generally prefer pre-trained representations, but not for every term, and it is quite close for many prompts. Specifically, `GloVe` pre-trained word embeddings achieve on average—for the set of political queries—80% of human performance and are generally preferred to locally trained embeddings.

  These results suggest embeddings estimated on large online corpora (e.g. Wikipedia and Google data dumps) can reasonably be used for the analysis of contemporaneous political

---

[27]This is lower in the case of small corpora like the State of the Union, and in the case of random queries for the Spanish corpus.

texts.

Further, if one does wish to train locally, the computational overheads are (not especially) severe, at least for a medium size corpus, so this is probably not a reason *per se* to use pre-trained embeddings.

Second, in terms of methodology lessons on *how* to evaluate models:

- **Query search:** in the absence of a clearly defined evaluation metric—a downstream task with labeled data—embeddings can be compared in terms of how they "organize" the embedding space. We propose doing so using query search ranking correlations for a set of randomly selected queries and—given a specific domain of interest— a set of representative domain-specific queries. To discriminate between models resulting in very different embedding spaces, both can be compared to a baseline, either a model known to perform well or, as we do, a human baseline.

- **Crowdsourcing:** Crowdsourcing provides a relatively cheap alternative to evaluate how well word embedding models capture human semantics. We had success with a *triad task* format, a choice-task with an established track-record and solid theoretical grounding in psychology.

- **Human "Turing" test:** a given embeddings model—or any model of human semantics for that matter—can be said to approximate human semantics well if, on average, for any given cue, the model generates associations (nearest neighbors) that a human cannot systematically distinguish from human generated associations.

  Specifically, we define human performance as the point at which a human rater is indifferent between a computer and a human generated association.

Third, in terms of 'instability'

- **Stability:** word embeddings methods have a lot of moving parts many of which introduce an element of randomness into the estimation. This produces additional variability beyond sampling error which, if unaccounted for, can lead to mistaken and non-replicable inferences.

To account for estimation-related instability we endorse estimating the same model several times, each with different randomly drawn initial word vectors and use an average of the distance metric of choice.[28] The good news, from our results at least, is that embeddings that perform well on the technical and human metrics tend to also be the most stable. Finally as an aside, the embeddings themselves should *not* be averaged as they lie in different spaces.

9 Discussion

Word embeddings in their modern scalable form have captured the attention of academia and industry, with the foundational papers in this area accumulating tens of thousands of citations since publication just five or six years ago. Early indications are that their influence will soon be felt in social science, especially in the study of politics. As always, more methodological options are better, but it is important that we understand what they can do for us and what they cannot.

Here, we focused on "optimal" specifications, for which we used multiple criteria both technical and substantive on what we deem to be a representative corpus—*The Congressional Record*. This included a new "Turing"-style test, which pits models (including cheap, pre-trained ones) against humans, to discover what (other) humans prefer. For the domain of political science, we have good news: by all the criteria we used, off-the-shelf pre-trained embeddings work very well relative to—and sometimes better than—both human coders, and more involved locally trained models. Furthermore, locally-trained embeddings perform similarly—with noted exceptions— across specifications which should reduce end-user angst about their parameter choices. The general form of these findings extend to historical and non-English texts.

Our efforts here has been concerned with a broad but necessarily limited number of possible options. Of course, other researchers will care about different substantive concepts and technical specifications. Irrespective of those particularities, however, our work-flow here will be useful. Finally, of course, we have focused on *relative* performance: we have not studied whether embed-

---

[28]Note, all packages initialize word vectors randomly so this simply amounts to estimating the same model several times.

31

dings are interesting or useful *per se* for understanding behavior, events and so on. We leave such questions for future work.

A   Task Wording

Context Words

A famous maxim in the study of linguistics states that:

You shall know a word by the company it keeps. (Firth, 1957)

This task is designed to help us understand the nature of the "company" that words "keep": that is, their CONTEXT.

Specifically, for a CUE WORD, its CONTEXT WORDS include words that:

> - Tend to occur in the vicinity of the CUE WORD. That is, they are words that appear close to the CUE WORD in written or spoken language.
>
> AND/OR
>
> - Tend to occur in similar situations to the CUE WORD in spoken and written language. That is, they are words that regularly appear with other words that are closely related to the CUE WORD.

For example, CONTEXT WORDS for the cue word COFFEE include:

1. *cup* (tends to occur in the vicinity of COFFEE).
2. *tea* (tends to occur in similar situations to COFFEE, for example when discussing drinks).

(a) Context Words

Task Description

For each iteration of the task (13 in total including trial and screener tasks):

1. You will be given a cue word (top center of the screen) and two candidate context words (on either side of the cue word).

2. Please select the candidate context word that you find best meets the definition of a context word.

3. We are especially interested in context words likely to appear in **political discourse.**

4. If both are reasonable context words, please select whichever you find most intuitive.

5. You must select **one and only one** of the two candidate context words.

Keep in mind, some iterations are for screening purposes. These are tasks for which there is clearly a correct answer.

Wrong answers in these screening tasks will automatically end your participation so **be sure to read carefully.**

The trial task that follows is meant for you to practice. Like screening tasks, the trial task has a correct answer.

Figure 7: Jaccard Index Between Pre-Trained and Local Models

B Jaccard Index

To further evaluate the correspondence between pre-trained embeddings and local models we use the average Jaccard-index —also known as the intersection over the union (IoU)—over the set of random and politics queries (Sahlgren, 2006; Pierrejean and Tanguy, 2017). The Jaccard-index between two models for a given query corresponds to the number of common nearest neighbors in the top N (the intersect of the two sets), over the union of the two sets. For example, take the following two sets of top 5 nearest neighbors for the query word democracy: $A = \{$freedom, democratic, ideals, vibrant, symbol$\}$ and $B = \{$freedom, democratic, dictatorship, democratization, socialism$\}$. Given two nearest neighbors in common, the IoU is $\frac{|A \cap B|}{A \cup B} = \frac{2}{8} = 0.25$. Figure 7 plots the Jaccard-index, for various values of N, between GloVe pre-trained embeddings and several local models varying by window size. Unlike with the Pearson correlations we do not subset the respective vocabularies. As with the Pearson correlations, we observe larger values as window-size increases but with decreasing returns.

C Window Size and Discrimination for a real corpus

The claim is that larger windows mean that we can better discriminate between term meanings. We looked at the evidence for this on our *Congressional Record* corpus. To assess the claim we

first set up a set of 'true negatives'—words that should be (fairly) unrelated. In particular for us, these are just random pairs of words from our corpus. We also evaluated how the average distance varies for 'true positives', that is words that are in fact the same. To assess this we sampled 100 words from the vocabulary. Suppose `congress` is one of those 100 words. We then. . .

1. tag half of the appearances (randomly selected) of `congress` in the corpus as `congress_tp`. So, if `congress` appears 10,000 times, in our transformed corpus it will appear as `congress` 5000 times, and `congress_tp` 5000 times.

2. estimate a set of embeddings with the vocabulary including both `congress` and `congress_tp`.

Now we have an embedding for `congress` and `congress_tp`. These should be close in embedding space, since they are the same word albeit (randomly) half the incidences have been given a different token (hence we call them "true positives"). We interpret *how* close they are as measure of performance.

In Figure 8a we plot the mean difference in similarity terms between the true positives and the true negatives. When this number is large, we are saying similar words look much more similar to one another than random words (i.e. our model is performing well). When this number is smaller, the model is telling us it cannot distinguish between words that are genuinely similar and words that are not. On the left of the figure, fixing the embedding dimensions at 300, we see that larger windows translate to bigger differences—i.e. the model performs better in terms of discrimination. We call this *meaningful separability*. [29] As an aside, on the right of the figure, we see that for a fixed window-size of 6, increasing the number of dimensions actually causes the model to do worse.

---

[29]Keep in mind, removing words from a corpus prior to processing into input-target pairs effectively enlarges the window-size (Levy, Goldberg and Dagan, 2015). This need only really be of concern when interested in syntactic relationships which requires smaller windows.

(a) Varying Window-Size (dimensions = 300)   (b) Varying Dimensions (window-size = 6)
Figure 8: Mean Difference in Cosine Similarity True Positives vs. True Negatives

D   Pre-trained embeddings perform equally across subgroups for *Congressional Record*

Above we showed that overall `GloVe` pre-trained embeddings correlate highly with locally trained embeddings. Next we ask whether these correlations differ by party. Such biases can be problematic if pre-trained embeddings are subsequently used to analyze texts and draw conclusions on the basis of party. To evaluate whether pre-trained embeddings exhibit bias we compare query search results based on pre-trained embeddings to results based on locally trained embeddings specific to each group (Democrat and Republican legislators). We say pre-trained embeddings exhibit bias—according to this metric—if query search results correlate significantly higher with the query search results of one group relative to other.

This evaluation requires we estimate separate embeddings for each of these groups. To do so, we split the congressional corpus by party (Republican vs Democrat). We apply the same estimation framework as laid out in section 4 to each sub-corpora except we fix window-size and embedding dimension at 6 and 300 respectively.

Figures 9a and 9b display the main results of our evaluation for a random set of queries and our set of politics queries respectively. For neither set of queries do we find evidence of partisan
